Abstract—The memristor can be used as non volatile memory (NVM) and for emulating neuron behavior. It has the ability to switch between low resistance R_{on} and high resistance values R_{off} , and exhibit the synaptic dynamic behaviour such as potentiation and depression. This paper presents a study on potentiation and depression of memristors in Quad Flat Pack. A comparison is drawn between the memristors with and without the impact of parasitics of packaging, using measured data and equivalent circuit models. The parameters in memristor and packaging models for the SPICE simulations were determined using measured data to reflect the memristor parasitics in Quad Flat Packs.

Index Terms—Memristors, IC package, Quad Flat Pack, Synaptic Dynamics

I. INTRODUCTION

Memristors are nonlinear devices that has the potential to drive the development of more than Moore’s law integrated circuits. Single memristor itself can store multilevel values which is controlled by the voltage or current applied across the device as a function of time. Ideally, it can be programmed to any resistance level between a maximum possible resistance R_{off} and minimum possible resistance R_{on} [1]. Memristors have small area, fast read times, low leakage currents which makes it promising non-volatile memory device. They are also known to be useful in neuromorphic applications as they exhibit the dynamics similar to the time-dependent changes in synaptic connections that alter the synaptic weights in neural networks (NN). If the memristor is exposed to the same stimuli over and over again, the change in memristance value of devices decreases over time, which is similar to the learning process of neurons. This is called long-term potentiation or long-term depression [2] of synapses.

Actual memristor devices are mathematically represented with extended memristor models. However, the existing models do not include switching stochasticity, which is important for extensive simulations of circuits prior to the fabrication. The realistic simulation of systems on chip with memristors require models that include memristance variations for R_{on} and R_{off} states and parasitics values associated with packaging that affects the circuit behaviour. As writing and erasing time of memristors are in nanoseconds range, the high frequency operation of the devices should be tested as well.

The aim of this paper is to analyse the impact of memristance variability and packaging on memristive devices. The parameters of equivalent circuit (R, L, C values) of packaged memristor used in this work were selected to model bond wires used in Quad Flat packs or Ball grid arrays which are of the interest for the low cost solution. Despite the speed limitation of Quad Flat Packs, its design can still be modified to provide higher speed of operation as in [3]

The remaining of the paper is organized as follows: Section II presents the details on the experimental setup of memristance measurements and memristor model modification. Section III introduces the equivalent circuit of packaged memristors and provides simulation results of both ideal outputs and the errors associated with a packaging effect.

II. DETERMINING MEMRISTOR MODEL PARAMETERS

There are different type of materials that memristors are fabricated such as Hafnium [4], Titanium [5], and Tungsten [6]. Depending on the material stack and structure of memristor device the ratio of R_{on} and R_{off} values, switching times, and switching threshold values can vary dramatically. The read and write pulse voltages, and the ON time period needs to be carefully selected to observe the memristor characteristics. Figure 1 presents the experimental setup for measuring R_{on} (a) and R_{off} memristance values of the memristor [7], that consists of (4) Keithley 4200 Parametric Analyzer [8], (3) DIP chip, containing 8 discrete memristors, (2) twisted wires that connect (1) the test fixture 8101-4TRX with the source and measure units to the pins of the memristor in a package.

A. Experimental setup and measurement results

For this paper, memristance measurements of chalcogenide memristors [7] in 16-pin DIP package were performed for only two states that correspond to high resistance R_{off} and low resistance R_{on} . The memristors used in the experimental measurements are sensitive to high voltage amplitudes and they best operate with stimuli of nanosecond width. The parametric analyzer shown in Fig.1 was used for generating square voltage pulses with 140ms width and $\pm 0.5V$ amplitude. The data collected from the experiment was limited to the 100 writing and erasing cycles in order to avoid damaging the memristors.

TABLE I
MEASURED MEMRISTANCE VALUES

	Mean (μ)	Max	Min
R_{off}	2924.655	7682.6	1432.4
R_{on}	323.4	512.03	305.34

The memristor chips are in the early stages of its development and have large device variability in terms of R_{on} and R_{off} values and the switching thresholds. For measuring the R_{on} and R_{off} variations of memristors, they have to be programmed to its respective state and read with the voltage lower than its switching threshold. In this paper, the memristance values were obtained altering the applied voltage to $+0.5V$ for writing and $-0.5V$ for erasing and $0.05V$ for

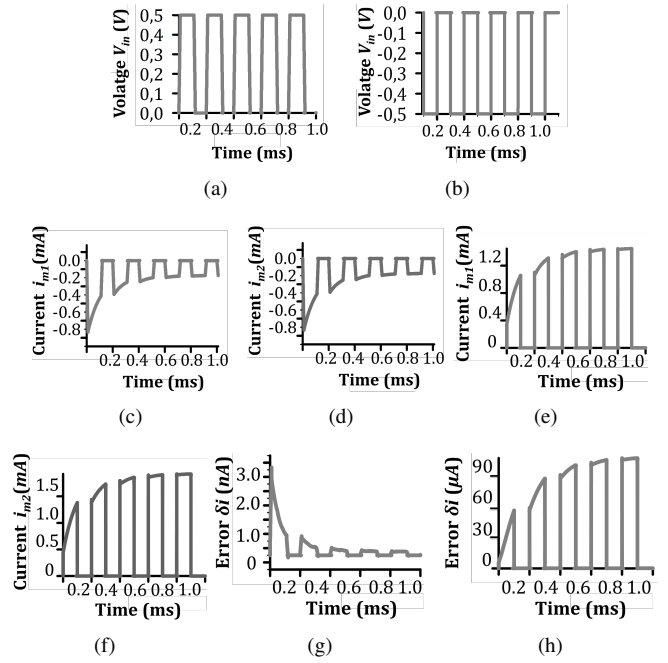

Fig. 4. Input and output values of the circuit using memristor model with $R_{on} = R_{on}^{mean}$, $R_{off} = R_{off}^{mean}$. (a) Voltage frequency is $10kV_{in} = 0.5V$; (b) Voltage frequency is $10kV_{in} = -0.5V$; (c, e) output current of packaged memristor circuit and (d, f) ideal circuit and (h, i) the δi respective error for $V_{in} = \pm 0.5V$.

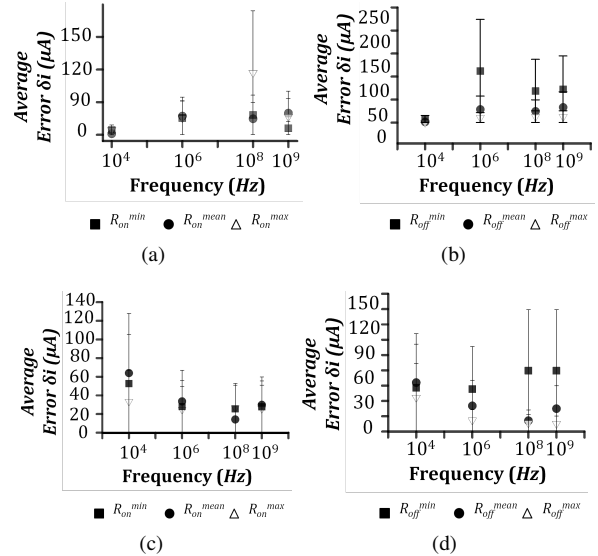

Fig. 5. Calculated average output current error with varying (a) R_{off} and (b) R_{on} values for the range of operating frequencies (10KHZ, 1MHz, 100MHz, 1GHz) with $V_{in} = 0.5V$; Calculated average output current error with varying (c) R_{off} and (d) R_{on} values for the range of operating frequencies (10KHZ, 1MHz, 100MHz, 1GHz) with $V_{in} = -0.5V$;

reading. The switching threshold of memristor used in the experiment was $0.15V$. The histograms presented in Figure 2 shows distribution of memristance values for R_{on} and R_{off} states. Table 1 shows the maximum, minimum and mean values of R_{on} and R_{off}

B. Modification of model parameters

For the simulation of packaged memristors the Known model [9] was used. In this model the lowest R_{on} and highest R_{on} memristance states were initially defined as 500Ω and 1500Ω respectively. The model parameters were modified replacing the R_{on} and R_{on} states with experimental data. The corner analysis and simulations are performed on five different combinations of memristor values, $\{R_{on}, R_{off}\}$, they are: (1) $\{R_{on}(\mu), R_{off}(\mu)\}$, (2) $\{R_{on}(\mu), R_{off}(\max)\}$, (3) $\{R_{on}(\mu), R_{off}(\min)\}$, (4) $\{R_{on}(\max), R_{off}(\mu)\}$, and (5) $\{R_{on}(\min), R_{off}(\mu)\}$.

III. ANALYZING THE ERROR ASSOCIATED WITH PACKAGE

In this section, the equivalent model of packaged single memristor is presented and simulation results of both ideal and packaged memristor circuits are provided.

A. Equivalent model of packaged memristor

Using memristors in circuits involves designing additional programming circuitry for setting the memristance values to R_{on} , R_{off} or other intermediate values. Depending on whether the memristor is at in programming mode (it is connected to the writing circuit at the input and shorted out at the output) or operating mode (it is connected to the readout circuit at the output) the equivalent circuit of interconnections between the memristive circuit and the electronic package will differ.

Figure 3a shows the equivalent model of the packaged memristor, while Fig. 3b shows an ideal case. The resistance values R_1 and R_2 represents the circuit blocks to which the memristor is connected. At the input of memristor's positive terminal R_1 represents the resistance of the writing circuit with low impedance. The output of the memristor circuit can be shorted out with a low R_2 or connected to the high impedance readout circuit. For the generalization of the circuit, we used R_1 and R_2 as 10Ω and approximated Quad Flat Pack parameters for wire inductance $L = 1.2nH$ and capacitance to ground $C = 25fF$ (capacitance to the substrate is ignored) as in [10].

B. Simulation results and Error analysis

In this section, the error associated with package parasitics is calculated for five cases of memristor resistance combinations as outlined in Section IIB. For the calculation of difference between ideal circuit output and packaged memristor circuit, a train of square voltage pulses V_{in} with frequency in the range from $10kHz$ to $1GHz$ was used as an input to the circuit. Fig. 4 shows the example of V_{in} at $10kHz$ (Fig.4a) and the corresponding current output of packaged memristor i_{m1} (Fig.4c) and memristor circuit without parasitic effect i_{m2} (Fig.4d). Fig.4g shows the error δi which is calculated as the difference between the current outputs i_{m2} and i_{m1} .

$$\delta i = i_{m1} - i_{m2} \quad (1)$$

The graphs Fig. 4(c) and Fig. 4(d) show the potentiation effect, while Fig. 4(e) and Fig. 4(f) show the depression effect

of memristance values during the first millisecond (0-1ms). For further estimation of error variations, the average error was calculated for the first 5 cycles of V_{in} with different frequencies. Figure 5 shows the overall trend of a substantial increase in the average error and its standard deviation with an increase in frequency and resistance values. It also shows the range of average error expected for variations of R_{on} (Fig.5 a,c) and R_{off} (Fig.5 b,d) values. For instance, driving the $0.5V$ to the input of the circuit at frequency $10kHz$, the current output should be expected with the error ranging from $1.6\mu A$ to $7.5\mu A$ while at $1GHz$ frequency the error range is larger, i.e., from $10\mu A$ up to $72\mu A$.

IV. CONCLUSION

In this paper, we presented the impact of variability of memristances and Quad Flat Packs in the realistic memristive devices. The data collected from experimental measurements reveals that the synaptic dynamics of memristors are affected with packaging. Performed modifications and the equivalent model of parasitics provide extended evaluation of error associated with the packaging effect on memristor switching dynamics. Such analysis will be useful in development of realistic neural circuits and systems with memristors and memristor arrays.
